(Received 12 December 2014; published 16 April 2015)

We demonstrate that waves in distinct layers of a neuronal network can become phase locked by common spatiotemporal noise. This phenomenon is studied for stationary bumps, traveling waves, and breathers. A weak noise expansion is used to derive an effective equation for the position of the wave in each layer, yielding a stochastic differential equation with multiplicative noise. Stability of the synchronous state is characterized by a Lyapunov exponent, which we can compute analytically from the reduced system. Our results extend previous work on limit-cycle oscillators, showing common noise can synchronize waves in a broad class of models.

Introduction. Nonlinear waves arise in many physical, biological, and chemical systems, including nonequilibrium reactions [1], shallow water [2], bacterial populations [3], epidemics [4], and cortical tissue [5]. Phase synchronization of multiple waves can occur when their dynamics are coupled. For example, spiral waves in chemical systems become entrained when coupled diffusively through a membrane [6]. Experiments on amoeba populations have also demonstrated entrainment via interactions between wave-emitting centers and spiral waves of cell density [7]. Common forcing can also synchronize waves at distinct spatial locations. Spatiotemporal analysis of epidemics reveals that both seasonality and vaccination schedule can entrain the nucleation of outbreak waves across geographical space [8]. Furthermore, activity recordings from the primary visual cortex show that triggering switches during binocular rivalry leads to synchronized wave initiation [9]. In total, experimental studies demonstrate a wide array of mechanisms for synchronizing the onset and propagation of waves.

Our goal in this Rapid Communication is to show that stochastic forcing can also entrain the phases of distinct waves. We focus on neural activity waves that arise due to distance-dependent synaptic interactions [5,10]. Waves of neural activity underlie sensory processing [11], motor action [12], and sleep states [13]. Proposed computational roles of neural activity waves include heightening the responsiveness of specific portions of a network and labeling incoming signals with a distinct phase [10]. Thus, it may be advantageous for waves to be coordinated across multiple brain areas, and we propose that correlated fluctuations may underlie such coordination. Many theoretical and experimental studies have identified ways noise correlations can degrade neural information encoding [14], but recent work has shown correlated noise can reliably synchronize activity across populations of neurons [15].

Our analysis extends previous work which showed common noise can synchronize the phases of limit-cycle oscillators [16,17]. A key observation of these studies is that the synchronous state, where all oscillators have the same phase, is absorbing when each oscillator receives identical noise. Stability of the phase-locked state can then be determined by computing an associated Lyapunov exponent, which is negative for nontrivial phase response curves [17]. As we show in this Rapid Communication, these principles can be applied to waves forced by common spatiotemporal noise. Waves are driven to an attracting synchronous state, where the waves’ phases are identical.

Synchronization of neural activity waves across distinct network locations can be important in several behavioral and sensory contexts. For instance, waves of activity in the visual cortex may function as a “barcode scanner,” ensuring a portion of the network is always maximally sensitive to external inputs [10]. Since locations in visual space are represented by multiple layers of a network, coordinating background waves across layers could ensure the network is always sensitive at the same visual location in each layer. Thus, our findings implicate an important potential role for large-scale correlations in nervous system fluctuations, which are often deemed a nuisance to cognitive performance [14].

In this Rapid Communication, we analyze the stochastic dynamics of waves in a pair of uncoupled neural field models driven by common noise. Neural fields are nonlinear integrodifferential equations whose integral term describes the connectivity of a neuronal network [18,19]. Recent studies have considered stochastic versions of neural field equations, formulating the dynamics as Langevin equations with spatiotemporal noise [19,20],

\[ du_j(x,t) = [-u_j(x,t) + w \ast f(u_j)]dt + \varepsilon dW(x,t), \]

where \( u_j(x,t) \) is the neural activity of population \( j = 1,2 \) at \( x \in [-\pi,\pi] \) at time \( t \), synaptic connectivity is described by the convolution \( w \ast f(u) = \int_{-\pi}^{\pi} w(x-y)f[u(y,t)]dy \), and \( f(u) \) is a nonlinearly describing the fraction of active neurons. Small amplitude \( (\varepsilon \ll 1) \) spatiotemporal noise \( dW(x,t) \) is white in time and correlated in space, so \( \langle dW(x,t) \rangle = 0 \) and \( \langle dW(x,t)dW(y,s) \rangle = 2C(x-y)\delta(t-s)dt ds \). As noise correlations must thus be even and 2\( \pi \) periodic, we write \( C(x) = \sum_{k=0}^{\infty} a_k \cos(kx) \).

Stationary bumps. We begin by demonstrating noise-induced wave synchronization for a single realization of the system Eq. (1) in Fig. 1(a) [21]. Here \( w(x-y) = \cos(x-y) \) is an even symmetric lateral inhibitory weight function, known to lead to stable stationary bump solutions in the unperturbed system \( (\varepsilon \equiv 0) \) [18]. Additive spatiotemporal noise causes each bump to wander diffusively about the spatial domain.

\[ zpkilpat@math.uh.edu \]
wave’s relative phase $\Delta_j$. A solution to Eq. (2) exists if we require the right-hand side to be orthogonal to the null space of the adjoint operator $L^* p = -p + f'(U) \cdot w \ast p$. Define $V$ to be a one-dimensional basis of $\mathcal{N}(L^*)$. Taking the inner product of Eq. (2) with $V$, we find
\[ \langle V(x), \varepsilon^{-1} d\Delta_j U_j'(x) + dW(x + \Delta_j, t) \rangle = 0, \]
so $\Delta_j$ obeys a Langevin equation with multiplicative noise,
\[ d\Delta_j = \varepsilon \int_{-\pi}^{\pi} \frac{V(x)dW(x + \Delta_j, t)dx}{\int_{-\pi}^{\pi} V(x)U'(x)dx}, \quad j = 1, 2. \]
We can represent $W(x, t)$ using the Fourier expansion
\[ W(x, t) = a_0X_0 + \sum_{k=1}^{\infty} a_k[X_k \cos(kx) + Y_k \sin(kx)], \]
where $X_k$ and $Y_k$ are white noise processes $X(k) = \langle Y(t) = 0 \rangle$ and $\langle X_k(t)X_l(t) \rangle = \delta_{kl}(t - s); \delta_{kl}$ is the Kronecker delta function. Using trigonometric identities, we can express
\[ d\Delta_j = \sqrt{2\varepsilon}dW(\Delta_j, t), \quad j = 1, 2, \]
where
\[ W(\Delta, t) = \sum_{k=1}^{\infty} [b_{+k} \cos(k\Delta)X_k + b_{-k} \sin(k\Delta)Y_k], \]
and the $X_0$ vanishes since $\int_{-\pi}^{\pi} V(x)dx = 0$ and $b_{\pm k}$ describe the relative contributions of each term of the Fourier series, Eq. (5), to the phase-dependent sensitivity of the oscillators to noise.

The synchronized solution $\Delta_1(t) = \Delta_2(t)$ to Eq. (6) is absorbing since the right-hand sides of both equations ($j = 1, 2$) will subsequently be identical. To assess the stability of the absorbing state, we compute the associated Lyapunov exponent $\lambda$. Proper calculation requires translating Eq. (6) into its equivalent Itô formulation [26],
\[ d\Delta_j = \varepsilon^2 R(\Delta)dt + \sqrt{2\varepsilon}dV(\Delta, t), \quad j = 1, 2, \]
where the Itô Eq. (7) introduces the drift term
\[ R(\Delta) = \sum_{k=1}^{\infty} [b^2_{+k} - b^2_{-k}]k \sin(k\Delta) \cos(k\Delta), \]
accounting for the fact that the correlation between state variables and noise terms, present in the Stratonovich Eq. (6), subsequently vanishes. We proceed by formulating the variational equation for the perturbative phase difference $\phi(t) = \Delta_1(t) - \Delta_2(t)$ ($\phi \ll 1$), which can be derived from Eq. (7), so
\[ d\phi = \varepsilon^2 R'(\Delta)dt + \sqrt{2\varepsilon}d\phi \gamma(\Delta, t), \]
where
\[ \gamma(\Delta, t) = \sum_{k=1}^{\infty} b_{+k} \cos(k\Delta)X_k - b_{-k} \sin(k\Delta)Y_k \]
and $\Delta$ obeys Eq. (7). Defining $\psi = \ln \phi$ and appealing to Itô’s formula, we can rewrite Eq. (9) as
\[ d\psi = \varepsilon^2 [R'(\Delta) - S(\Delta)]dt + \sqrt{2\varepsilon}d\gamma(\Delta, t), \]
where
\[ S(\Delta) = \sum_{k=1}^{\infty} k^2 \left[ b^2_{+k} \sin^2(k\Delta) + b^2_{-k} \cos^2(k\Delta) \right]. \]  
(11)

Subsequently, we can integrate Eq. (10) to determine the mean drift of \( \lambda(t) \),
\[ \lambda := \varepsilon^2 \lim_{t \to \infty} \int_0^t \left[ R'(\Delta(s)) - S(\Delta(s)) \right] ds, \]
(12)

which is also the mean rate of growth of \( \phi(t) \). The phase difference \( \phi(t) \) will tend to decay (grow) if \( \lambda < 0 \) (\( \lambda > 0 \)) and synchrony will be stable (unstable). Utilizing the ergodicity of Eq. (10), we can equivalently compute \( \lambda \) with the ensemble average across realizations of \( \lambda(\Delta,t) \), so [17]
\[ \lambda = \varepsilon^2 \int_{-\pi}^{\pi} P_s(\Delta)[R'(\Delta) - S(\Delta)]d\Delta, \]
(13)

where \( P_s(\Delta) \) is the steady state distribution of \( \Delta \). Since noise is weak (\( \varepsilon \ll 1 \)), we can approximate the distribution as constant, \( P_s(\Delta) = 1/(2\pi) \). Applying this to Eq. (13), we find the first term of the integrand vanishes since \( R(\pi) = R(-\pi) \) according to Eq. (8), so the Lyapunov exponent is approximated by the formula
\[ \lambda = \lim_{t \to \infty} \varepsilon^2 \int_{-\pi}^{\pi} S(\Delta)d\Delta = -\frac{\varepsilon^2}{2} \sum_{k=1}^{\infty} k^2 \left[ b^2_{+k} + b^2_{-k} \right]. \]
(14)

Note that as long as \( b_{+k} \neq 0 \) or \( b_{-k} \neq 0 \) for some \( k \ll \infty \), we expect \( \lambda < 0 \), so the phase-locked state \( \Delta(t) = \Delta_s(t) \) will be linearly stable.

We now compare the analytical result Eq. (14) to results from numerical simulations of Eq. (1). Explicit calculations are straightforward in the case of a Heaviside nonlinearity \( f(u) = H(u - \theta) \), cosine weight function \( w(x) = \cos(x) \), and cosine spatial noise correlations \( C(x) = \cos(x) \). Stable stationary bump solutions are given by the formulas \( U(x) = 2 \sin a \cos x \) and \( \dot{U}(\pm a) = \dot{\theta} \), and the null vector \( V(x) = b(x - a) - b(x + a) \) [23]. Coefficients of the noise Fourier components in Eq. (5) are \( a_k = \delta_{k1} \), so \( b_k = \pm 1/(\sqrt{1 - \theta} + \sqrt{1 + \theta}) \) and \( b_{-k} \equiv 0, k \neq 1 \). Finally, utilizing Eq. (11) along with Eq. (14), we have
\[ \lambda = -\frac{\varepsilon^2}{2} \left[ b^2_{+1} + b^2_{-1} \right] = -\frac{\varepsilon^2}{2 + 2\sqrt{1 - \theta^2}}. \]
(15)

Results from numerical simulations in Figs. 1(b) and 1(c) corroborate with Eq. (15), showing the Lyapunov exponent’s magnitude \( |\lambda| \) increases with noise intensity \( \varepsilon^2 \) and threshold \( \theta \). We note that our theoretical approximation breaks down as \( \theta \) increases and the system nears a saddle-node bifurcation at which the stable and unstable, branches of the bump solutions annihilate in the noise-free system [18,22,23]. Furthermore, the amplitude \( |\lambda| \) increases as the parameter \( \theta \) is increased towards this bifurcation.

We show the robustness of these results by studying the impact of independent noise [Fig. 2(a)]. To do so, we consider a modified version of Eq. (1), \( du_j = \left[ -u_j + w * f(u_j) \right] dt + \varepsilon dW_j \), where \( W_j \) has an independent component in each layer \( j = 1,2 \) (see the Appendix). Extending the analysis of limit-cycle oscillators [27], we derive an expression for the stationary density
\[ M_0(\phi) = \frac{m_0}{g(0) - \chi^2 g(\phi)} \]
(16)
of the phase difference \( \phi = \Delta_1 - \Delta_2 \). Here, \( \chi \in [0,1] \) is the degree of noise correlation, \( g(\Delta) = \sum_{k=-\infty}^{\infty} b^2_k \cos(k\Delta) \) (\( b_k = |b_k| \)), and \( m_0 \) is a normalization constant. As \( \chi \) is decreased from unity, the stationary density widens, representing the effects of independent noise in each layer. However, the density will still tend to peak at \( \phi = 0 \) (see the Appendix). Indeed, our theory, Eq. (16), is corroborated by numerical simulations [Fig. 2(b)].

**Traveling waves.** Our results for stationary bumps can be extended to address stochastic synchronization of traveling waves in networks with asymmetric weights \( [w(x) \neq w(-x)] \), as in Fig. 3(a). Thus, the unperturbed system, \( \varepsilon \to 0 \) in Eq. (1), will have traveling wave solutions \( u_j(x,t) = U(\xi - x_j) \), \( \xi = x - ct \), with wave speed \( c (j = 1,2) \), so \( -cU'(\xi) = -U(\xi) + w * f(U) \) [22,28]. Furthermore, waves will be neutrally stable to translating perturbations, so spatiotemporal noise will cause an effective diffusion of their phases. For \( \varepsilon > 0 \), we apply the ansatz \( u_j(x,t) = U(\xi - \Delta_j(t)) + \varepsilon \Phi_j(\xi - \Delta_j(t),t) + O(\varepsilon^2) \)

![FIG. 3. (Color online) Noise-induced phase locking of traveling waves evolving in Eq. (1) with \( w(x) = \cos(x - \varphi) \). (a) Noise perturbations drive wave phases to the phase-locked state \( \Delta_j(t) = \Delta_s(t) \). Here \( \varphi = 0.2 \), while other parameters are as in Fig. 1. (b) The Lyapunov exponent \( \lambda \) calculated from numerical simulations (circles) is approximated by Eq. (17) (line), increasing in amplitude \( |\lambda| \) with the skewness \( \varphi \) of the weight function [21].]

![FIG. 2. (Color online) Independent noise prevents complete phase locking (see the Appendix). (a) Noise correlations drive the bumps close to one another \( [\Delta_1(t) \approx \Delta_2(t)] \), but independent noise prevents their remaining in the phase-locked state. (b) Stationary density \( M_0(\phi) \) widens for \( \chi < 1 \) in Eq. (16) theory (line) and numerics (circles). Parameters are \( \theta = 0.5, \varepsilon = 0.01, \chi = 0.95, \) and \( C_j(x) = \cos(x) (j = 1,2,\varepsilon) \).]
with $\Delta_j(t) = x_j$ and will show $\lim_{t \to \infty} |\Delta_j(t) - \Delta_2(t)| = 0$. At $O(\epsilon)$, we find Eq. (2) with a corresponding linear operator $L u = cu - u + w \ast f'(U) \cdot u$. Solvability is enforced by ensuring the right-hand side of Eq. (2) is orthogonal to the null space $V$ of the adjoint $L' p = -cp' + p + f'(U) \cdot w(-\xi) \ast p(\xi)$, yielding the Langevin equation, Eq. (4). The Lyapunov exponent $\lambda$ associated with the stability of the absorbing state $\Delta(t) = \Delta_2(t)$ is then approximated by Eq. (14).

To compare our analytical results for traveling waves with numerical simulations, we compute $\lambda$ from Eq. (14) when $f(u) = H(u - \theta)$, $w(x) = \cos(x - \varphi)$, and $C(x) = \cos(x)$. Stable traveling waves have a profile $U(\xi) = \cos[\sin(\xi - \sin(\xi + a))]$, width $a = \pi - \sin^{-1}[\theta \sec \varphi]$, and defined by thresholds $U(\xi_1) = U(\xi_2) = 0$ where $\xi_1 = \pi - a$ and $\xi_2 = -\pi$, and speed $c = \tan \varphi$ [28]. The null vector can also be computed explicitly:

$$V(\xi) = \sum_{k=1}^2 (-1)^k \left[ H(\xi_2 - \xi_k) + \frac{\cos(\pi/c - 1)}{2} \right] e^{(\xi - \xi_k)/c}.$$

Fourier coefficients of $\mathcal{W}(\Delta, t)$ in Eq. (6) are thus given $b_{k,1} = (1 + c)/2 - (c \pm 1) \sin a/[2(1 - \cos a)]$ and $b_{k,2} \equiv 0$, $k \neq 1$, so we compute Eq. (14), finding

$$\lambda = -\frac{c^2}{2} \left[ b_{k,1}^2 + b_{k,2}^2 \right] = -\frac{c^2(1 + \cos a)}{2a^2},$$

(17)

comparing with the numerical results in Fig. 3(b).

Breathers. Lastly, we show that uncoupled oscillatory waves can also become phase locked due to a common noise source. We extend Eq. (1) by incorporating linear adaptation as an auxiliary variable $q_j(x,t)$ ($j = 1, 2$) and a spatially varying external input $I(x)$ [29–31],

$$du_j = [-u_j - \beta q_j + w \ast f(u_j) + I]dt + \epsilon dW, \quad (18a)$$
$$dq_j = \alpha[u_j - q_j], \quad j = 1, 2, \quad (18b)$$

where $\alpha$ and $\beta$ are the rate and strength of adaptation. A detailed analysis of the onset of breathers in Eq. (18), via a Hopf bifurcation, can be found in Refs. [30,31].

Our main interest is the rate at which breathers in a pair of uncoupled neural fields synchronize their phases when subject to common noise as in Eq. (18). An example of this phenomenon is shown in Fig. 4(a). Note, we must take care in interpreting how the centers of mass of each oscillating bump relate to the phase of the underlying oscillation. In the case of bumps and waves, there was a one-to-one mapping between the wave positions $\Delta_j$ and the phase of the stochastically driven oscillator. Here, we must track the activity $u_j$ and adaptation $q_j$ variables to resolve the phases $\vartheta_j$ of the underlying oscillations. Assuming breathers have period $T$, $u_j(x,t) = u_j(x,t + T)$ and $q_j(x,t) = q_j(x,t + T)$, so $\vartheta_j(t) = \vartheta_j(t + T)$, and there is a mapping $(u_j, q_j) \mapsto \vartheta_j$ for all values $(u_j, q_j)$ along the trajectory of a breather. We save a more detailed analytical determination of this mapping for future work. Here, we numerically determine $\vartheta_j$ (t), average, and compute the rate of decay $\lambda$ using the approximation $A + \lambda t \approx \frac{1}{T} \sum_{j=1}^N \ln |\vartheta_j(t) - \vartheta_2(t)|$ using least squares [Fig. 4(b)]. Note, in the case of bumps, the Lyapunov exponent increases in amplitude as it nears the pattern-generating (Hopf) bifurcation.

Discussion. Our results demonstrate that common spatiotemporal fluctuations in neuronal networks can synchronize the phases of waves. We have shown this for stationary bumps, traveling waves, and breathers. Since our derivations mainly rely on our ability to derive an effective equation for the relative position of a noise-driven wave, we suspect we could extend them to the case of traveling fronts [25] or Turing patterns [20] in stochastic neural fields. Patterns on two-dimensional (2D) domains could also be addressed by deriving multidimensional effective equations for each pattern's position. For instance, a bump's position would be represented with a 2D vector [32], so there would be two Lyapunov exponents associated with the bumps' phase-locked state. On the other hand, spiral waves could be characterized by a 2D position vector and a scalar phase [33], and phase- and position-locked states would then have three Lyapunov exponents. We could also consider interlaminar coupling [34], exploring the competing impacts of common noise and coupling on phase synchronization as in Ref. [35]. Furthermore, these results should be applicable to nonlinear partial differential equation (PDE) models of reaction-diffusion systems [24,36]. Overall, our results suggest a mechanism for generating coherent waves in laminar media, presenting a testable hypothesis that could be probed experimentally.

Appendix. Here, we analyze the stochastic dynamics of bumps in a pair of uncoupled neural field models driven by both common and independent noise sources, extending previous work on limit-cycle oscillators [27]. We incorporate an independent noise term into each layer of the stochastic neural field model [34]:

$$du_j(x,t) = \left[ -u_j(x,t) + \int_{-\pi}^{\pi} w(x - y) f[u_j(y,t)]dy \right] dt$$
$$+ \epsilon \left[ dW_j(x,t) + \sqrt{1 - \chi^2} dW_0(x,t) \right].$$

(21)

Small amplitude ($\epsilon \ll 1$) spatiotemporal noise terms $dW_j(x,t)$ ($j = 1, 2, c$) are white in time and correlated in space.
so \( \langle dW_j(x,t) \rangle = 0; \langle dW_j(x,t) dW_j(y,s) \rangle = 2C_j(x-y) \delta(t-s) dt ds \) (j = 1,2,c) with \( C_j(x) = \sum_{k=0}^{\infty} a_k \cos(kx) \). The degree of correlation between layers is controlled by the parameter \( \chi \).

Our analysis proceeds by considering stationary bumps in a network with even symmetric connectivity \([w(x) = w(-x)]\). As in the main text, we characterize stochastic bump motion by applying the ansatz \( u_j(x,t) = U(x - \Delta_j(t)) + \varepsilon \Phi_j(x - \Delta_j(t), t) + O(\varepsilon^2) \), and \( \Delta_j(0) = x_j \). Plugging this ansatz into Eq. (A1), expanding to \( O(\varepsilon) \), and applying a solvability condition, we find that each \( \Delta_j \) (j = 1,2) obeys the Langevin equation

\[
d\Delta_j = \varepsilon \chi \int_{-\pi}^{\pi} V(x) dW_j(x + \Delta_j, t) dx + \varepsilon \sqrt{1 - \chi^2} \int_{-\pi}^{\pi} V(x) U'(x) dx,
\]

\( j = 1,2 \), where the first and second terms correspond to correlated and independent noise. Here, \( V \) is a one-dimensional basis of \( L^*(L^*) \), where \( L^* = \{p(x) = -p(x) + f'(U(x)) \int_{-\pi}^{\pi} w(x-y) p(y) dy \} \). Since \( U(x) \) is even symmetric, all components of the null space of \( L^* \) are necessarily odd symmetric \([23]\). Note, we can represent \( W_j(x,t) = a_0 X_0^{(j)} + \sum_{k=1}^{\infty} a_k^{(j)} [X_k^{(j)} \cos(kx) + Y_k^{(j)} \sin(kx)] \) (j = 1,2,c), where \( X_k^{(j)} \) and \( Y_k^{(j)} \) are normalized white noise processes. We can thus use trigonometric expansions to express

\[
d\Delta_j = \sqrt{2\varepsilon} \chi \int_{-\pi}^{\pi} V(x) dW_j(x + \Delta_j, t) dx + \varepsilon \int_{-\pi}^{\pi} V(x) U'(x) dx,
\]

\( j = 1,2 \), where \( W_j \) are multiplicative noise terms defined as

\[
W_j(\Delta, t) = \sum_{k=1}^{\infty} [b_{+k}^{(j)} \cos(k\Delta) X_k^{(j)} + b_{-k}^{(j)} \sin(k\Delta) Y_k^{(j)}],
\]

and since \( V(x) \) is odd symmetric, \( X_0 \) vanishes, and

\[
b_{\pm k} = \pm a_k \int_{-\pi}^{\pi} V(x) \cos(kx) dx - \int_{-\pi}^{\pi} V(x) U'(x) dx.
\]

Equation (A2) can be reformulated as an Itô equation \( d\Delta_j = B_j(\Delta_j) dt + d\zeta_j(\Delta_j, t) \), where \( \zeta_j(\Delta, t) = \sqrt{2\varepsilon} \chi \int_{-\pi}^{\pi} V(x) (\Delta + \Delta_j) dx + \varepsilon \int_{-\pi}^{\pi} V(x) U'(x) dx \) (j = 1,2) has correlations defined as \( \langle d\zeta_j(\Delta, t) d\zeta_k(\Delta, t) \rangle = C_{jk}(\Delta) \) (j = 1,2,k = 1,2), and the drift \( B_j(\Delta) = \frac{1}{2} \frac{\partial}{\partial \Delta} C_j(\Delta) \) (j = 1,2). Components of the correlation matrix are given as

\[
C_{jk}(\Delta) = 2\varepsilon^2 (\chi^2 + \delta_{jk}(1 - \chi^2)) \sum_{m=1}^{\infty} b_m^2 \cos[m(\Delta_j - \Delta_k)],
\]

where \( \Delta = (\Delta_1, \Delta_2) \) and \( b_k = |b_{\pm k}| \), so it is straightforward to compute \( B_j(\Delta) = 0 \) (j = 1,2).

The corresponding Fokker-Planck equation, describing the coevolution of the position variables \( (\Delta_1, \Delta_2) \), is thus

\[
\frac{\partial P(\Delta, t)}{\partial t} = \varepsilon^2 g(0) \left[ \frac{\partial^2 P(\Delta, t)}{\partial \Delta_1^2} + \frac{\partial^2 P(\Delta, t)}{\partial \Delta_2^2} \right] \\
+ 2\varepsilon^2 \chi^2 \frac{\partial^2}{\partial \Delta_1 \partial \Delta_2} [g(\Delta_1 - \Delta_2) P(\Delta, t)],
\]

(A3)

where \( g(\Delta) = \sum_{k=1}^{\infty} b_k^2 \cos(k\Delta) \). Note, since \( b_k^2 \geq 0 \), \( \varepsilon(\Delta) \) is odd symmetric, all components of the null space of \( L^* \) are necessarily odd symmetric \([23]\). We can write Eq. (A3) as a separable equation by employing a change of variables that tracks the average \( \rho = (\Delta_1 + \Delta_2)/2 \) and phase difference \( \phi = \Delta_1 - \Delta_2 \) of the phase variables \( \Delta_1 \) and \( \Delta_2 \).

\[
\frac{\partial P(\tilde{\Delta}, t)}{\partial t} = \varepsilon^2 \left[ \frac{g(0)}{2} + \chi^2 g(\phi) \right] \frac{\partial^2 P(\tilde{\Delta}, t)}{\partial \phi^2} \\
+ 2\varepsilon^2 \chi^2 \frac{\partial^2}{\partial \phi^2} \left[ (g(0) - \chi^2 g(\phi)) P(\tilde{\Delta}, t) \right],
\]

(A4)

where \( \tilde{\Delta} = (\rho, \phi) \). Equation (A4) can be decoupled by plugging in the ansatz \( P(\tilde{\Delta}, t) = S(\rho, t) \cdot M(\phi, t) \) and noting the equation will be satisfied by the system

\[
\frac{\partial S(\rho, t)}{\partial t} = \varepsilon^2 \left[ \frac{g(0)}{2} + \chi^2 g(\phi) \right] \frac{\partial^2 S(\rho, t)}{\partial \rho^2},
\]

(A5)

\[
\frac{\partial M(\phi, t)}{\partial t} = 2\varepsilon^2 \chi^2 \frac{\partial^2}{\partial \phi^2} \left[ (g(0) - \chi^2 g(\phi)) M(\phi, t) \right].
\]

Thus, we can solve for the stationary solution of the system, Eq. (A5), by setting \( S(\rho) = M(\phi) \equiv 0 \) and requiring periodic boundary conditions. The stationary distribution for the position average is \( S_0(\rho) = 1/(2\pi) \). Furthermore, we can integrate the stationary equation for \( M(\phi, t) \) to find that the stationary density of the phase difference is

\[
M_0(\phi) = \frac{m_0}{g(0) - \chi^2 g(\phi)},
\]

(A6)

where \( m_0 = \int_{-\pi}^{\pi} [g(0) - \chi^2 g(\phi)] dx \) is a normalization factor. When noise to each layer is independent \( (\chi \to 0, \text{uncorrelated}) \), then \( M_0(\phi) = 1/(2\pi) \). Thus, all initial conditions eventually result in the phase-locked state \( \Delta_1 = \Delta_2 \). The stationary distribution \( M_0(\phi) \) broadens as \( \chi \) is decreased, with a peak still remaining at \( \phi = 0 \). To compare our results to numerical simulations, we compute the stationary density \( M_0(\phi) \) explicitly by using \( f(u) = H(u - \theta), w(x) = \cos(x), \) and \( C_j(x) = \cos(x) \) (j = 1,2,c). Stable stationary bumps \( U(x) = 2 \sin a \cos(x) \) satisfy the threshold condition \( U(\pm a) = \theta \), with half width \( a \). We can thus compute the null vector \( V(x) \) by solving \( \delta(x - a) - \delta(x + a) \) and find \( b_{\pm k} = \pm 1/[\sqrt{1 + \theta} + \sqrt{1 - \theta}] \) and \( b_{\pm k} \equiv 0, k \neq 1 \). Therefore,

\[
M_0(\phi) = \frac{\sqrt{1 - \chi^2}}{2\pi [1 - \chi^2 \cos(\phi)]},
\]

(A7)
[21] Numerical simulations used the Euler-Maruyama method along with a direct spectral method for evaluating integrals. Time steps $dt = 0.01$ and spatial steps $dx = 2\pi/1000$. Numerically evaluated Lyapunov exponents were determined by averaging $\ln |\Delta_2(t) - \Delta_2(0)|$ across $N = 5000$ realizations and fitting to $\lambda t$ using MATLAB’s polyfit function.
